The screenshot displays the Google Earth Engine web interface. The top navigation bar includes the Google Earth Engine logo and a search bar. Below the navigation bar, there are tabs for 'Scripts', 'Docs', and 'Assets'. The 'Scripts' tab is active, showing a script titled 'Forests_Droughts/LST_MODIS *'. The script code is as follows:

```
1 var area = ee.FeatureCollection(geometry);
2 //var area = ee.FeatureCollection(geometry);
3 var startDate = '2020-01-01';
4 var endDate = '2020-12-31';
5
6 // Load LST data
7 var LST = ee.ImageCollection('MODIS/006/MYD11A1')
8   .filter(ee.Filter.date(startDate, endDate))
9   .select('LST_Day_1km');
10 var LST = LST.map(function(image) { return image.clip(area); });
11
12 // change LST from kelvin to celcius
13 var LST = LST.map(function(img) {
14   return img
15     .multiply(0.02)
16     .subtract(273.15)
17     .copyProperties(img, ['system:time_start']);
18 });
19
```

The right-hand side of the interface shows the 'Inspector' panel, which displays the properties of the selected point (13.378, 52.522) at 2Km/px. The 'Pixels' section shows the 'Land Surface Temperature: Image (1 band)' with a mean value of 27.074047619047654. The 'Objects' section shows the 'Land Surface Temperature: Image (1 band)' with a type of 'Image', a list of 1 band, and 1 property.

The bottom half of the screenshot shows a map of Europe with a heatmap overlay. The heatmap uses a color scale from green (low temperature) to red (high temperature). The map includes labels for various countries and cities, such as Ireland, England, Wales, Guernsey, Jersey, Belgium, Nederland, Polen, Tschechien, Slowakei, and Österreich. The map also shows major cities like London, Paris, Amsterdam, Warsaw, and Krakau.

ABSTRACT

As a result of ongoing climate change and more frequent heat events, the regulating services of land cover in terms of moderating and mitigating local temperatures are increasingly important. While the reduced temperatures found in forests and wetlands are recognized, their wider contribution to regional landscape cooling remains largely uncharacterized and unquantified. Herein, we propose and test a new method that estimates the temperature response and inertia of landscapes in high temperatures, based on land cover share. In order to achieve this goal, we combined the MODIS daytime land surface temperature (hereafter LST) time series and CORINE land cover data. We classified the time series in two ways, i.e. by stepwise temperature range (−10/−5 °C to +25/+40 °C) and by the occurrence of hot days (days with a mean LST ≥ 30 °C). As an explanatory variable, we developed and used a generalised composite of the MODIS normalized difference vegetation index (NDVI) time series. In our study area, covering parts of northeastern Germany and western Poland, the fragmented landscape has heterogeneous temperature patterns, including urban heat islands, warm agricultural areas, cool forests and cold wetlands. We found that at high temperature ranges only forests and wetlands remained comparably cool, with LSTs up to 20.8 °C lower than the maximum LST in the study area. The analysis of land cover shares and LSTs revealed the substantial cooling effect of forests and wetlands in line with increasing land cover share in higher temperature ranges, as well as on hot days. The relation between LST and the NDVI indicated vegetation cover as the cause. We propose the corresponding metrics to quantify landscape-level temperature regulation. Equally, we advocate for management to identify these ecosystem services and their current and potential contributions, along with implications for sustaining and increasing, both tree cover and wetlands and thereby adapting landscapes to climate change.

1. Introduction

Increases in temperature, which are among the most dangerous impacts of climate change, threaten socioeconomic activities (Chen et al., 2020), ecosystem functioning (Fisher et al., 2017) and human health (Luber and McGehee, 2009; Mora et al., 2017). Human mortality estimates based on data from climate-related heat exposure and deaths in 732 locations over 43 countries suggest a mean of 37.0% (range 20.5–76.3%) between 1991 and 2018, with increased mortality seen on all continents (Vieira-Cabreira et al., 2021). Heat also contributes to other climate-related challenges such as increased water-stress and drought (Fisher et al., 2017; Teuling et al., 2013). One way to avoid these negative effects is to prevent or moderate temperature extremes (Hatfield and Prueger, 2015).

The relationship between remotely sensed *land surface temperature* (LST) and land cover has been investigated in various contexts (Aljama and Coscuti, 2016; Bosa, 2008; Bright et al., 2017; Jin and Dickinson, 2010). Different land covers are associated with different thermal properties, especially the heat island effects that occur in urban and other built-up areas (Bartasaghi-Koc et al., 2020; Feizizadeh and Blaschke, 2013; Liu et al., 2018; Su et al., 2018; Tran et al., 2017). Land cover proportion has been used in a study of an urban area to investigate to what extent landscape metrics can explain LST (Liu et al., 2018), as well as for a vegetation fraction cover analysis (Duvellier et al., 2018;
